We investigate the drag experienced by a spherical intruder moving through a medium consisting of granular hydrogels immersed in water as a function of its depth, size, and speed. The medium is observed to display a yield stress with a finite force required to move the intruder in the quasistatic regime at low speeds before rapidly increasing at high speeds. In order to understand the relevant time scales that determine drag, we estimate the inertial number \( I \) given by the ratio of the time scales required to rearrange grains due to the overburden pressure and imposed shear and the viscous number \( J \) given by the ratio of the time scales required to sediment grains in the interstitial fluid and imposed shear. We find that the effective friction \( \mu_e \) encountered by the intruder can be parametrized by \( I = \sqrt{\rho_g/P_p v_i} \), where \( \rho_g \) is the density of the granular hydrogels, \( v_i \) is the intruder speed, and \( P_p \) is the overburden pressure due to the weight of the medium, over a wide range of \( I \) where the Stokes number \( St = I^2/J \gg 1 \). We then show that \( \mu_e \) can be described by the function \( \mu_e (I) = \mu_0 + \alpha I^\beta \), where \( \mu_0 \), \( \alpha \), and \( \beta \) are constants that depend on the medium. This formula can be used to predict the drag experienced by an intruder of a different size at a different depth in the same medium as a function of its speed.

I. INTRODUCTION

Objects moving through a viscoplastic medium composed of granular materials sedimented in a liquid are encountered widely at the bottom of water bodies and in the processing of petroleum and consumer products [1]. While a number of studies have investigated the force acting on an object moving through noncohesive granular matter in air [2–6] and in liquids [7], a robust friction law for the drag encountered by the intruder is not available. In the case of a granular medium immersed in a liquid where grains are always in contact, friction encountered has been found to be unchanged from the dry case [8]. Above this quasistatic limit, the intruder motion leads to inhomogeneous fluidization of the medium, giving rise to challenging problems in modeling their dynamics [9,10]. Because sedimented grains are densely packed and in contact, the granular stress can be expected to increase with depth, leading to sensitive variation in the dissipation encountered by an intruder as a function of depth. Furthermore, the relative importance of the granular and fluid components of the medium on the drag experienced by the intruder in this context remains undetermined.

Rheological properties of viscoplastic media are typically fitted to the Herschel-Bulkley model and its variations that relate the stress applied to the medium to the resulting strain rate of the medium [11,12]. Further, progress has been made recently [13–15] in describing the effective friction encountered by granular materials sheared uniformly under steady-state conditions using the inertial number \( I \). This parameter, which is proportional to the strain rate, characterizes the ratio of the time scale over which grains rearrange due to pressure and the time scale required for grains to move past each other due to applied shear. In the case of neutrally buoyant non-Brownian suspensions immersed in a fluid, a constitutive law has been also proposed as a function of the viscous number \( J \) that characterizes the ratio of the time scale over which grains sediment and the time scale over which they rearrange due to applied pressure under steady-state conditions [16]. Further numerical simulations appear to suggest that the effective friction encountered by a uniformly sheared granular medium immersed in a fluid can be described by a combination of \( I \) and \( J \), as \( K = \gamma I^2 + J \), where \( \gamma \) is a constant that depends on the relative importance of inertia and viscosity of the medium [17]. However, it remains unclear how these descriptions can be extended to transient systems and ones in which the solids have a higher mass density compared to the liquid as in the case of sedimented solids.

Here we probe the dynamics of an intruder moving through sedimented granular hydrogels immersed in water as a function of the properties of the intruder and the medium. We use this medium as a model because it enables a subtle examination of inertia, gravity, and viscosity on the intruder dynamics. We focus our study on the condition where the intruder is pulled with a constant speed. However, it should be noted that the resulting intruder motion still leads to unsteady flow of the medium as it is fluidized and accelerated around the intruder. We obtain the inertial number \( I \) and the viscous number \( J \) to understand the relative importance of grain inertia and fluid viscosity on the observed dynamics. By measuring drag, we find that the effective friction \( \mu_e \) given by the ratio of the stress acting on the intruder and the overburden pressure can be parametrized by \( I \) over the range of experimental parameters investigated. We further discuss the overall form of the observed \( \mu_e \) as a function of \( I \), which can be used to relate the drag experienced at a particular depth and speed to an intruder with a different size moving with different speed and depth.

II. EXPERIMENTAL SYSTEM

A schematic of the experimental apparatus is shown in Fig. 1(a). A large rectangular tank with length \( L = 91 \) cm, width \( W = 45 \) cm, and height \( H = 42.5 \) cm is filled with granular hydrogels immersed in water in a temperature-controlled room maintained at 24.0 ± 0.5 °C. The tank size was chosen to...
be large enough that its boundaries do not affect the drag and thus the system can be considered as semi-infinite with only the distance to the bed surface playing a role in the measurements discussed in this study. The granular hydrogels were prepared by immersing dehydrated polyacrylamide particles in distilled water. Two sets of granular hydrogels with hydrated radius $r_h = 0.5 \pm 0.3$ and $8.5 \pm 0.5$ mm and density $\rho_h = 1004$ and 1006 kg m$^{-3}$, respectively, were used in the study. Because the grains are athermal and heavier than water (density $\rho_w = 998$ kg m$^{-3}$ at 24°C), they sediment to the bottom. A layer of clear water on the top prevents capillary effects from playing any role in the medium. The depth of this clear layer is not observed to have any measurable effect on the properties of the granular hydrogel medium below.

The volume fraction $\phi$ occupied by the sedimented granular hydrogels is estimated by measuring the volume of water displaced by the hydrogels. In the case of the smaller hydrogels, which are more polydisperse, we find $\phi \approx 0.5$, and in the case of the larger hydrogels, which are more monodisperse, $\phi \approx 0.6$, similar to sedimented frictional glass beads with similar size distribution [18]. Then the overburden pressure $P_p$ at depth $z$ due to the difference of density of the granular hydrogels and the water is given by $P_p = \phi(\rho_h - \rho_w)gz$, where $g$ is the acceleration due to gravity. Although the granular hydrogels are relatively soft with a Young modulus $E$, which is measured [19] to be $\approx 23$ kPa, the fractional change in their volume can be estimated from $P_p/E$ to be less than 0.1% at the deepest point in the tank. Thus, we assume that the density of the medium $\rho_m = \phi\rho_h + (1 - \phi)\rho_w$ is essentially constant for the purpose of our study. Substituting the values for $\rho_h$, $\rho_w$, and $\phi$, we obtain $\rho_m = 1001$ and 1003 kg m$^{-3}$ for the small and large granular hydrogels, respectively.

In order to further quantify the effect of grain elasticity, we evaluate both the time scale due to elasticity $T_k$ and the time scale due to gravity $T_g$ [20]. We estimate $T_k$ from the grain contact time scale $T_k = \sqrt{m/k_n}$, where $m$ is the grain mass and $k_n \approx 2Er_h$ is the grain stiffness assuming linear contact. We then estimate $T_g$ from the time taken by a grain to fall from rest through a distance $r_h$, i.e., $T_g = \sqrt{2r_h/g}$. We obtain $T_k/T_g \approx 1.5 \times 10^{-2}$ and $0.4 \times 10^{-2}$ in the case of the small and large hydrogels used in our study. The friction coefficient has been found to be relatively constant in numerical simulations for such contact times, relative to the time scale set by gravity [20].

A spherical intruder with a density similar to the hydrogels and radius $r_i$ is fixed to the end of a stiff thin rod with radius $r_r$ and immersed in the medium to a depth $z_i$ as shown in Fig. 1(a). The rod is attached to a torque sensor and is translated along the length of the tank with speed $v_i$. The measurements are performed in the central third of the tank to avoid any effects of the tank walls. Because the medium is semitransparent because the hydrogels have a refractive index that is close to the water, we can observe the motion of the intruder and the medium around it. A movie of the motion of the medium obtained using a laser sheet as the intruder advances through the medium is shown in the Supplemental Material [21]. One observes that the grains accelerate around the intruder and quickly come to rest after the intruder passes by, similar to what one may expect in a viscous liquid. However, because the motion of the grains was difficult to track using automated algorithms, we were unable to extract quantitative information from the imaging. Hence, we focus on the measurement of drag experienced by the intruder using the torque sensor attached to the intruder in this study.
The torque $T$ measured as function of time $t$ is plotted in Fig. 1(b) and is observed to fluctuate around a constant value for a prescribed value of speed $v_i$. The mean torque $〈T(t)⟩$ is then obtained by averaging over time. The torque acting at the pivot has contributions because of the drag due to the intruder as well as the rod that attaches to the intruder in the medium. Therefore, we perform complementary measurements to account for the drag contribution due to the rod. The measured torque $T_i$ as a function of the rod length immersed in the medium $l_r$ is plotted in Fig. 1(c) at various speeds in the case of $d_h = 0.5$ mm and can be fitted as shown with a quadratic dependence on $l_r$. This quadratic form of drag with an increase of the depth of the rod has been found previously in the case of a dry granular medium in the quasistatic limit \[22\] and can be understood as follows. If the drag increases linearly with depth, then $T_i = F_d^2(z_p + \frac{1}{2}l_r)$, where $z_p$ is the distance from the pivot to the medium surface as shown in Fig. 1(a). Indeed, as shown by the fit, we find that the torque increases quadratically with $l_r$, consistent with a linear increase of drag for a section of the rod with depth. This torque contribution is thus subtracted from the total mean torque to extract an approximate estimate of the torque $T_i$ due to the intruder alone. Then we determine the drag acting on the intruder as $F_d = T_i/(z_p + l_r)$.

Further, we find that a systematic protocol has to be used while preparing the medium in order to obtain consistent data. In particular, drag measurements were conducted after stirring the medium, then allowing it to settle, and then waiting a fixed amount of time before pulling the intruder through the medium. Figure 1(d) shows the evolution of the measured drag $F_g$ as a function of wait time $t_w$ after the medium is stirred. One observes a significant variation over the first few minutes after the sediments are allowed to settle. The behavior stabilizes after approximately 10 min. Therefore, we use a wait time of 15 min before doing the systematic drag measurements as a function of system parameters reported in this study.

**III. MEASUREMENT OF DRAG**

The drag $F_d$ measured as a function of the intruder speed $v_i$ is plotted in Fig. 2(a) in the case of the media composed of the small and the large granular hydrogels but otherwise similar conditions. The data are plotted in a log-linear format to emphasize the wide range of intruder velocities probed. In each case, one observes that $F_d$ appears essentially constant and well above zero at low $v_i$ and increases rapidly as the velocity increases above $v_i \sim 1$ mm s$^{-1}$. Further, one observes that $F_d$ is higher in the case of the larger grains compared with the smaller grains at low $v_i$, before crossing over as $v_i$ is increased. Thus, the relative drag experienced by an intruder appears to depend on not only the medium, as one may expect, but also its speed.

To understand the measured drag in relation to the drag corresponding to the Newtonian fluid in which the grains are immersed, we obtain the estimate using $F_d^\eta = \frac{3}{2} C_d v_i^2 r_i^2$, where $C_d$ is the drag coefficient of sphere. Then, using the approximation \[23,24\] $C_d \approx 24/\text{Re}(1 + 0.15 \text{Re}^{0.687})$, where Re is the Reynolds number given by $\text{Re} = \rho_w v_i r_i / \eta$, with the dynamic viscosity of water $\eta = 0.91$ mPa s, we calculate $F_d^\eta$ and plot it in Fig. 2(a) over the same range of velocity. It is noted to be considerably smaller than the measured drag in the granular medium. Thus, although the hydrogel sediments have

- FIG. 2. (a) Measured drag $F_d$ for an intruder as a function of $v_i$ in the medium composed of the two different sized grains investigated in our experiments, but otherwise similar conditions. The error bars correspond to the standard deviation. The estimated drag in water for the same intruder size is also plotted for reference and is observed to be significantly lower than for the granular hydrogel medium. (b) Drag as a function of intruder speed $v_i$ for various overburden pressures $P_o$ corresponding to various depths ($r_h = 0.5$ mm). The errors in the measurement are similar to the graph above but are not drawn for clarity. (c) Drag as a function of intruder size $r_i$ at various speeds along with a quadratic fit in the case of each velocity ($r_h = 0.5$ mm).
Parameters, we define an effective friction that increases rapidly with increasing drag experienced by the intruder as a function of system parameters. We plot the measured drag experienced by the intruder versus the gravitational force due to the weight of the grains acting on the intruder, i.e., $F_d \propto \rho_d r_i^2$. However, it should be noted that this scaling can be expected to hold provided the intruder size is larger than the grain size, with a more tortuous motion expected for smaller size grains. We also plot the measured drag as a function of the radius of the intruder as the observed variation with speed and depth. These include the time scale imposed on the grains due to the motion of the intruder, the time scale over which grains rearrange due to applied pressure, and the sedimentation time scale. By comparing these time scales, we can determine the relative importance of these variables, which are affected by $v_i$ and $P_p$ on the observed drag.

IV. EFFECTIVE FRICTION

To understand the observed variation of drag with system parameters, we define an effective friction $\mu_e$ experienced by the intruder as the ratio of the drag to the normal forces acting on the intruder. Estimating the normal force acting on the intruder as the overburden pressure times its cross-sectional area, we have

$$\mu_e = \frac{F_d}{P_p \pi r_i^2}.$$  \hspace{1cm} (1)

With this definition, it can be noted that $\mu_e$ is independent of the intruder size because $F_d$ is proportional to $r_i^2$, as seen from Fig. 2(c).

Focusing now on the depth dependence, $\mu_e$ as a function of $v_i$ is plotted in Fig. 3(a) for various $P_p$ in the case of $r_h = 0.5$ mm and in Fig. 3(b) in the case of $r_h = 8.5$ mm. We observe that $\mu_e$ corresponding to the different $P_p$ appear to collapse at low $v_i$ in the quasistatic regime, but clearly do not overlap for $v_i > 10^{-1}$ m s$^{-1}$ even considering the errors in the measurements. Above this value, it appears that $\mu_e$ is effectively lower at greater depths for the same speeds. Thus, we conclude that the effective friction grows relatively less quickly with depth above the quasistatic regime as the grains are increasingly imparted momentum by the intruder.

A. Inertial and viscous numbers

We next examine the relative time scales in the system to understand the observed variation with speed and depth. These include the time scale imposed on the grains due to the motion of the intruder, the time scale over which grains rearrange due to applied pressure, and the sedimentation time scale. By comparing these time scales, we can determine the relative importance of these variables, which are affected by $v_i$ and $P_p$ on the observed drag.

We first consider the inertial number $I$ corresponding to the ratio of the time scale for grains to rearrange due to the pressure and the time scale over which grains move past each other due to the shear resulting from the intruder motion. This dimensionless number is used to understand the significance of dynamic features in granular systems [13,14] and is given by $I = \gamma d/\sqrt{P/d}$ in the case of grains with size $d$ and density $\rho$, which are sheared uniformly with shear rate $\dot{\gamma}$ under pressure $P$. Because the intruder system is unsteady even when the intruder moves at constant velocity—the medium is accelerated as it moves around the intruder—a steady-state shear rate cannot be defined in our system. Nonetheless, we assume that the time scale relevant to the motion of the hydrogel grains is set by the velocity of the intruder and is thus inversely proportional to the shear rate $\dot{\gamma} = v_i/r_h$. Further, assuming the pressure $P \sim P_p$ and the grain density $\rho \sim \rho_h$, we have the time scale relevant to rearrange grains to be $\sqrt{P_p/\rho_h}/r_h$. Thus,

$$I = \frac{v_i}{\sqrt{P_p/\rho_h}}.$$  \hspace{1cm} (2)

Figure 4(a) shows $I$ plotted as a function of $v_i$ for various $P_p$. We observe that $I$ varies over many orders of magnitude as $v_i$ and $P_p$ are varied in our experiments from below $10^{-3}$ associated with the quasistatic regime to above $10^0$ associated with the collisional regime. Further, $I$ obtained in the case of both hydrogel sizes fall on the same line that scales with $v_i$.
We then consider the viscous number $J$, which captures the relative importance of the time scales due to sedimentation of grains and shear [16]. This dimensionless number is given by $J = \eta_s \dot{y} d / P$, where $\eta_s$ is the viscosity of the liquid. As in the case of the inertial number, $J$ was introduced for uniform shear rates. Assuming $\dot{y} d \sim v_i$ as in the estimate of $I$, we obtain

$$J = \frac{\eta_s}{2P_p \rho_h} v_i.$$  \hspace{1cm} (3)

The viscous number $J$ versus $v_i$ is plotted in Fig. 4(b) with $\eta_s = \eta$ corresponding to the viscosity of water at $24^\circ$C. We observe that $J$ also varies over a wide range as a function of $v_i$ and $P_p$ investigated in the experiments, but is significantly smaller in magnitude compared to $I$. Further, $J$ for the larger hydrogels is approximately a magnitude smaller than in the case of smaller hydrogels, because the sedimentation rate for larger particles is higher than for the smaller particles with the same density.

To further understand the relative importance of the inertial time scale and the sedimentation time scale, we examine the Stokes number $St$, which is given by $St = I^2 / J$. Substituting in Eqs. (2) and (3), we have

$$St = \frac{\rho_h v_i}{\eta_s}.$$  \hspace{1cm} (4)

Plotting $St$ in Fig. 4, we observe that it varies between 10 and $2 \times 10^4$ in the case of the larger hydrogels and between 0.2 and $10^3$ in the case of the smaller hydrogels. Thus, the drag encountered appears to be in the inertial regime except in the case of the lowest velocities probed for the smaller grains. Accordingly, the inertial number appears to be the appropriate nondimensional number to describe the rate dependence of the friction as probed by the intruder velocity.

### B. Rate dependence of effective friction

We plot the effective friction $\mu_e$ versus $I$ in Figs. 5(a) and 5(b) for the small and large sized grains, respectively, investigated in our experiments. In contrast with the plots of $\mu_e$ versus $v_i$ in Fig. 3, we find that $\mu_e$ for the various $P_p$ clearly collapse onto a single curve for each grain size. Thus, one concludes that the stress acting on the intruder due to drag scales linearly with the pressure. A similar conclusion was reached [20] based on numerical simulations of dry granular materials investigating the role of pressure on the contact stiffness and its impact on the effective friction encountered in a granular medium. There, a deviation from linearity was found only at high pressures correlated with changes in the volume fraction of the medium. Because no significant volume fraction changes were noted in our experimental system over the range of overburden pressures encountered, the observed collapse of $\mu_e$ with $P_p$ in Fig. 4 is consistent with that study. Further, one can note that $\mu_e$ is essentially constant over the range $10^{-4} \leq I \leq 10^{-2}$, consistent with the range typically associated with a quasistatic flow regime in granular media [26]. We further tested if the collapse improves by plotting $\mu_e$ versus $K$ using $\gamma$ as a variable [17]. No marked improvement is observed beyond what is shown in Fig. 5.

To understand the observed form of $\mu_e$ with $I$ above the quasistatic regime, we examine the scaling for $\mu_e$ above the effective friction coefficient in the quasistatic regime $\mu_0$ with the form

$$\mu_e(I) = \mu_0 + \alpha I^\beta,$$  \hspace{1cm} (5)

where $\alpha$ and $\beta$ are fitting constants. The value of $\beta$ in particular can provide insight into the nature of the medium as probed by the intruder. Noting that $\mu_e$ is proportional to the stress at a given depth and $I$ is proportional to the shear rate, this form is similar to the Herschel-Bulkley model for stress and strain rate...
in which case one may expect Bagnold inertial granular rheology in which the medium behaves like a viscous fluid above yield with viscosity proportional to the medium exchange momentum during rapid collisions.

We also fit the data by fixing $\beta = 1$ in Eq. (5) and display the result in Fig. 5 to test if the simpler Bingham model can describe the observed $\mu_e(I)$. Systematic deviations can be observed as captured by the greater dispersion in the fitting parameters that are listed in the figure caption. Thus, we conclude that the drag experienced by the intruder found at a given depth and speed can be used to predict the drag that the intruder will experience at a different set of depths and speeds using the function given in Eq. (5).

We further test if the fit of $\mu_e$ with the empirical functional form proposed by Jop et al. [26] for steady-state flows can describe the data $\mu_e(I) = \mu_0 + (\mu_1 - \mu_0)/(I_0/I + 1)$, where $\mu_1$ and $I_0$ are constants that depend on the medium. Such a function implies that $\mu_e$ increases from $\mu_0$ as $I/I_0$ increases toward 1 and then increases toward $\mu_1$ as $I/I_0$ becomes well above 1. While this form also appears to give a good description of the data, we find that fitting constants do not converge with $\mu_1$ and $I_0$ diverging with the increasing number of iterations used in the fitting.

Now comparing the relative values of effective friction, it can be noted that $\mu_e$ is lower at low speeds in the case of the smaller granular hydrogels compared with the larger hydrogels due to its lower volume fraction, which leads to fewer contacts between grains [28]. However, as the speed of the intruder is increased, the effective friction is observed to rise at a lower $I$ in the case of the smaller grains. This leads $\mu_e$ to be higher in the case of the smaller grains than the large grains for intermediate values up to $I \sim 1$. This appears to occur because of the relative greater importance of the fluid in the case of the smaller hydrogels as captured by the lower Stokes number. Further investigations are required to fully understand these variations that depend on the nature of the medium.

V. CONCLUSION

We have measured the drag experienced by an intruder that is pulled through a sedimented granular medium immersed in water. We found that the drag experienced depends on the size of the intruder, the intruder depth in the medium, and the intruder speed. Introducing an effective friction coefficient that corresponds to the average stress experienced by the drag and normalized by the overburden pressure, we found that the friction encountered by the intruder can be parametrized by using the inertial number, which increases with the intruder velocity and as the inverse square root of the overburden pressure.

We proposed an empirical formula for the observed variation of friction with the inertial number inspired by the Hershel-Bulkley model, which depends only on the properties of the medium. Using this friction law, it was possible to relate the drag experienced by a given spherical intruder at a given depth in the medium to an intruder at a different depth in the same medium. We also related the drag encountered by an intruder of a given size to that of a different size given the observation that drag increases quadratically with the intruder size. We have further shown that the properties of the
medium, including the granular packing and fluid, can impact the empirical constants in the formula. However, further work needs to be done to fully understand these empirical constants and the detailed contribution of each parameter of the medium to the friction encountered by the intruder.

Among the broader implications of our findings is that the inertial number can be used to describe the friction encountered by an intruder in a transient flow. The effective friction in the case of granular systems has previously been only clearly shown to depend on the inertial number under steady-state conditions. This understanding of the drag experienced by an intruder in an unsteady flow not only can lead to a better description of the dynamics of passive objects in sedimented granular medium, but also has implications for a better description of active motion of organisms through sand and clay using the observed rheology.
